ABSTRACT

Current hot issue of networked control systems (NCSs) remains how to optimize the signal transmission in imperfect links, especially, data missing (between the controller and actuator) is a potential source of poor performance of the control system. Here, stochastic variables satisfying markov jump process are used to describe the fading channel. Considering the uncertainty factor of plant, a practical compensation technique is utilized to minimize the effects caused by data dropout. Attention is paid to designing a useful control law to drive the closed-loop system stable and preserve a guaranteed infinite-horizon performance function, where the infinite-horizon control moves are parameterized as a free control move. Furthermore, the corresponding problems about recursive feasibility and stochastic stability are established by a set of linear matrix inequalities. Simulation results are shown to verify the performance of the proposed approach.

General Terms

Networked system, predictive control

Keywords

Data missing, polytoic model, state feedback.

1. INTRODUCTION

With the continuous advancements of communication technology, network has been inevitably introduced in control zone because of its advantages, such as low cost, simple installation, maintenance and high reliability ([9], [8], [1], [10]). Networked control systems are a class of feedback control system in structure, with control loops over networks for signals transmission, specifically, observations and feedback-control signals are transmitted through communication channels, computer can solve the complex optional algorithms, control theory lies in the core situation, respectively. However, considering the real time networked environment, the phenomenon of data loss is unavoidable due to the reasons of network congestion, limited bandwidth, etc [28]. Therefore, the issue about the optional performance and stability of NCSs becomes a hard work. Research on data loss gets much attention. So far, many achievements have appeared. To mention a few. In [24], a self-triggered sampling scheme is proposed for a networked control system with consideration of data losses and communication delays, by making use of this scheme, the next sampling instant does not depend on on-line estimation of an event-triggered condition and the successive measurement of the state. Paper [18] studies the exponential synchronization of complex dynamical networks with control packet loss and additive time-varying delays, a novel Lyapunov-Krasovskii functional (LKF) with triple integral terms is constructed and by using Jensen’s inequality and reciprocally convex approach, sufficient conditions under which the dynamical network is exponentially mean-square stable are derived. Considering both uniform and random consecutive data losses induced by long periods of transmission failure, a novel approach using a combination of prediction strategy and constant control gain based on gain error ratio (GER) is proposed for solving the problem by [20]. However, the above researches seldom use model predictive control method, which is an advanced optional algorithm.

Model predictive control (MPC) has a well-earned reputation in recent years, it provides on-line solutions to optimal feedback control problems, so model predictive control can be seen as a circular operation that a minimum problem is solved to calculated optional control inputs for a time horizon, specifically, at every instant, it requires the on-line solution of an optimization problem to compute optimal control inputs. Although more than one control sequences are calculated, only the first one is implemented, at next instant, the optimization problem is reformulated and solved with new measurements obtained from the system [15]. Besides, another advantage of model predictive is that it can be conveniently used to solve the input and parameter constraints. In addition, several industrial process models as well as many performance index of importance can be handled by predictive control, for some references, the stable problems are studied in [23], [13], [19]; the MPC for stochastic system is investigated in [13], [6], [26], [25], [21]; for MPC of fuzzy system in [29], [4], [1], [18], [16]. Moreover, model predictive control shows the advantages in dealing with the model uncertainties, the problem of designing predictive controllers that explicitly optimize and stable the uncertainty system has obtained much interests from researchers and many great results have been made; see, e.g. Due to many of the robust model-predictive controllers developed to-date suffer from excessively conservative control, paper [12] presents a model predictive controller that uses a closed-loop model to estimate the uncertainty in future process inputs and outputs, the new controller solves a stochastic program at each execution in order to determine
the set of control moves. A note ensured recursive feasibility in robust model predictive control with multiplicative uncertainty by applying terminal constraints to the degrees of freedom available to the controller while constructing polytopic tube cross sections, the technique in [24] by bounding the tube parameters in norm and constructing a terminal set based on this bound, which reduces the online computational load and so allows longer prediction horizons to be used. They propose an approach to design robust distributed model predictive control for polytopic uncertain networked control systems with time delays. An augmented polytopic uncertainty description is involved to handle the input delays and the conservativeness of distributed predictive control algorithm is reduced by using a sequence of feedback control laws. In [27], robust model predictive control (RMPC) is compared with nominal predictive for the purposes of fore-aft tower damping of large wind turbines, the two controllers are identical save for their handling of the multiplicative and additive uncertainty in the prediction horizon. State and input constraints are applied to a control model that is identified by data-driven methods.

From above all, although, a great achievements on networked control systems have been made in recent years, however, how to solve the unreliable networks remains difficult and the problem of stability of stochastic system also brings obstacles to researches. This paper, therefore, focus on the stochastic networked system wherein controller outputs are transmitted via communication networks. Data loss inevitably happens in the communication link and stochastic variables satisfying the Markov process are used to describe the imperfect channel. Attention is devoted to derived a suitable controller such that the closed-loop system is stability and preserves a guaranteed optional performance.

2. PROBLEM FORMULATION

The structure of NCSs concerned in this paper is shown in fig.1

![Diagram](image)

Fig. 1. The structure of networked control system (NCSs)

In fig.1 the plant, sensor, controller and actuator are spatially separated. \( x(k) \in R^{m \times n} \) is the state vector, \( u(k) \in R^{m \times m} \) is the control outputs and \( v(k) \in R^{m \times n} \) is a signal received by actuator, and \( k \geq 0 \) is sampling time (or time step).

Now, the models of the physical plant, controller and transmission links are as follow.

Plant: the plant selected in this paper is a discrete linear time varying (LTV) system sampling periodically with \( T > 0 \), which can be modeled as follows:

\[
\begin{align*}
    &x(k + 1) = A(k)x(k) + B(k)v(k) \\
    &y(k) = Cx(k)
\end{align*}
\]

(1)

Where the uncertainties are expressed by allowing the state-space matrices \( A(k), B(k) \) to be arbitrarily time varying and lying in a polytope \( \{A(k)B(k)\} \in \Theta = \text{Co}([A_1, B_1], \ldots, [A_l, B_l]) \), and \( \text{Co} \) represents the convex hull, \([A \ B] \text{ means} \) vertices of the convex hull and any \([A \ B] \text{ lying in} \ \Theta \) is a linear combinations of vertices \([A(k)B(k)] = \sum_{i=0}^{l} \sigma_i[A_i, B_i] \) for some non-negative \( \sigma_1, \ldots, \sigma_l \) summing to one. In this paper, the input constraints considered are the Euclidean norm constraints, that is, \( v(k + i) \leq v_{\text{max}} \).

Controller: Here a state-feedback control law is adopted.

\[
u(k) = Kx(k) \quad k \geq k_0
\]

Therefore, the corresponding predictive control law is:

\[
u(k + i) = Kx(k + i) \quad k \geq k_0, \quad i > 0
\]

(3)

Communication links: communication links exist between the controller and actuator, according to assumption, the controller only sends data at each sampling time \( k \geq 0 \), the actuator only receives data at each sampling time \( k \geq 0 \). All data are transmitted in a single packet at each time. Because of the stochastic data loss, the control outputs are no longer equivalent to the inputs of the actuator, i.e. \( u(k) \neq v(k) \), to deal with this phenomena, a compensation strategy is as follow:

\[
    v(k) = \lambda(k)u(k) + (1 - \lambda(k))\tau v(k - 1)
\]

(4)

Where \( \lambda(k) \in \{0, 1\} \) is a stochastic variable modeling the imperfect nature of the link from the controller to the actuator, \( \tau \in [0, 1] \) is a forgetting factor selected by user. Assuming the data loss process is a discrete-time Markov process (failure and recovering), the corresponding probability is \( P(\lambda(k) = 0 | \lambda(k) = 1) = \alpha \in [0, 1], \ P(\lambda(k) = 1 | \lambda(k) = 0) = \beta \in [0, 1], \) respectively. According to the compensate strategy, at sampling time \( k \), if data are received, \( v(k) = u(k) \), otherwise, \( v(k) = \tau v(k - 1) \) (zero-order hold effect).

By [1], [3], [4], defining \( \tilde{v}(k) = [x(k)^T \ v(k - 1)]^T \), where \( \tilde{v}(k) \in R^{m \times m} \), according to all above equations, the model of closed-loop stochastic-networked system with time delays can be obtained.

\[
    \tilde{v}(k + 1) = \psi(k, \lambda(k))\tilde{v}(k)
\]

(5)

where

\[
    \psi(k, \lambda(k)) = \begin{bmatrix}
        A(k) + \lambda(k)B(k)K(1 - \lambda(k))\tau B(k) \\
        \lambda(k)K(1 - \lambda(k))\tau I
    \end{bmatrix}
\]

Remark 1: For the closed-loop systems, the uncertainties come from the self-structure properties of the plant and stochastic variable \( \lambda(k) \). Considering the requirements of real-time of the physical plant, the sensor is clock-driven, controller and actuator are event-driven.

Remark 2: The paper assumes that data missing has an upper bound \( h_{\text{max}} \) (h successive loss), by the compensation strategy, the control inputs \( v(k) \) are stored in actuator buffer are applied to the system when failure transmission.

Now, the design about controller for the system [5] is shown as: Assuming that the system state is fully available, how to obtain a control law based on packet dropout such that the system [5] is stable and keep optional performance.
3. ROBUST MODEL PREDICTIVE CONTROL WITH ONE FREE CONTROL MOVE FOR NCSS

Given a common performance objective function as

\[
\min_{u(k+1)} \max_{A(k), B(k)} J_\infty^k (k)
\]

(6)

Where \( J_\infty^k (k) = J_L^k (k) + J_S^k (k), \) specifically, first stage cost \( J_L^k (k) = \hat{\gamma}^T (k) S \hat{y}^T (k) + v^T (k) R v(k), \) and terminal cost \( J_S^k (k) = \sum_{s=1}^{\infty} \{ \hat{\gamma}^T (s) S \hat{y}^T (s) + v^T (s) R v(s) \}, \) here, \( S = \text{diag}(S_1, 0), S_1 > 0 \) and \( R > 0 \) are reasonable weighting matrices.

Defining a quadratic Lyapunov function:

\[
V(x(k+i+1), v(k+i+1)) = x^T (k+i+1) Q_{\lambda(k+i+1)} x (k+i+1) + v^T (k+i+1) Q_{\lambda(k+i+1)} v (k+i+1)
\]

(7)

Satisfying \( V(0) = 0, \lambda(k+i) = w \in (0, 1) \) and the following constraint:

\[
E\{V(k+i+1) - V(k+i)\} \leq E \{ \hat{\gamma}^T (k+i) S \hat{y}^T (k+i) + v^T (k+i) R v(k+i) \}
\]

(8)

Summing up the inequality\(^6\) from \( i = 1 \) to \( \infty \), for the quadratic function to be finite, taking \( \lim_{i \to \infty} E\{V(k+i)\} = 0 \), so \( \lim_{i \to \infty} E\{V(k+i)\} = 0 \). Thus

\[
J_\infty^k \leq E\{V(k+1)\}
\]

Let

\[
x^T (k) S_1 x (k) + v^T (k) R v (k) + x^T (k+1) x (k) + v^T (k) G_{\lambda(k+1)} x (k) \leq \gamma (k)
\]

(9)

Where \( x(k) = x_{\lambda} \) is the state of the system at sampling instant \( k \). Therefore, the minimization of \( J_\infty^k \) is converted to getting the minimization of a variable \( \gamma \) subject to

\[
\min_{u(k+1)} \max_{A(k), B(k)} \gamma (k)
\]

S.t. \( \{5\}, \{6\}, \{9\}, \{9\} \)

(10)

3.1 Stochastic invariant constraints about system states

Lemma1:(Stochastic Invariant ellipsoid) Following \( \{5\}, \{3\}, \{22\} \), the states are as follow:

\[
\hat{\gamma} (k+i) \in \Omega = \{ \hat{\gamma} | \hat{\gamma}^T diag(Q_{1,i}, G_{1,i}^{-1}) \hat{\gamma} \leq 1 \}
\]

\[
\lambda (k+i) = 1 \ \text{and} \ \ V (k+i) \leq \gamma
\]

(11)

If there is a scalar \( \gamma (\gamma > 0) \), symmetric matrices \( Q_{1,i}, G_{1,i}, G_{0,i}, \) \( s = 1, \ldots, h_{\text{max}} \) and \( Y \) satisfy the following LMI's with \( i = 1, \ldots, l \):

\[
\begin{bmatrix}
Q_{1,i} & * & * & * \\
0 & G_{1,i} & * & * \\
A_i Q_{1,i} + B_i Y & 0 & Q_{1,i} & * \\
Y & 0 & 0 & G_{1,i}
\end{bmatrix} \geq 0
\]

(12)

In this case, \( \zeta = \{ \hat{\gamma} \hat{\gamma}^T diag(Q_{1,i}, G_{1,i}^{-1}) \hat{\gamma} \} \) is an invariant ellipsoid for the predicted states of the uncertainty system with a desired control gain \( K \) satisfying \( K = Y_{\text{opt}} \).

Proof: By assumption, the solution from optional performance control gain \( K \) satisfying \( K = Y_{\text{opt}} \). That is, \( \lambda (k+i) = 1 \), \( \lambda (k+i+1) = 1 \), if \( \{12\} \) satisfied, then \( \hat{\gamma}^T (k+i) S \hat{y}^T (k+i) + v^T (k+i) R v(k+i) = 0 \)

\[
\begin{bmatrix}
Q_{0,s} & * & * & * \\
0 & G_{0,s} & * & * \\
A_{0,s} Q_{0,s} + B_i G_{0,s} & 0 & Q_{0,s} & * \\
0 & \tau G_{0,s} & 0 & G_{0,s}
\end{bmatrix} \geq 0
\]

(14)

\[
\begin{bmatrix}
\hat{Q}_{0,s} & * & * & * \\
0 & \hat{G}_{0,s} & * & * \\
A_{0,s} \hat{Q}_{0,s} + B_i \hat{G}_{0,s} & 0 & \hat{Q}_{0,s} & * \\
0 & \tau \hat{G}_{0,s} & 0 & \hat{G}_{0,s}
\end{bmatrix} \geq 0
\]

(15)

\[
\begin{bmatrix}
Q_1 & * & * & * \\
0 & G_1 & * & * \\
A_i Q_1 + B_i Y & 0 & Q_1 & * \\
Y & 0 & 0 & G_1
\end{bmatrix} \geq 0
\]

(13)

\[
\begin{bmatrix}
Q_{0,s} & * & * & * \\
0 & G_{0,s} & * & * \\
A_{0,s} Q_{0,s} + B_i G_{0,s} & 0 & Q_{0,s} & * \\
0 & \tau G_{0,s} & 0 & G_{0,s}
\end{bmatrix} \geq 0
\]

(14)

At time \( k+2 \), two cases will be taken into account for \( \lambda (k+2) = 1 \) or \( \lambda (k+2) = 0 \). If \( \lambda (k+2) = 1 \), then \( \lambda (k+2) = 1 \), if \( \lambda (k+2) = 0 \), then \( \lambda (k+2) = 0 \).

\[
\text{Using } \{12\}, \text{it's easily get } \hat{\gamma}^T (k+2) \in \Omega; \text{ (ii) } 1 \rightarrow 0 \rightarrow 1, \text{ i.e. } \lambda (k+2) = 1, \lambda (k+1) = 0, \lambda (k+2) = 1, \text{ we define } \hat{\gamma} (k+1) \in \Omega_{0,i} := \{ \hat{\gamma} \hat{\gamma}^T diag(Q_{0,i}, G_{0,i}) \}. \text{ So only } \{13\}, \{14\}, \{15\} \text{ hold, we have}
\]

\[
\hat{\gamma}^T (k+2) \in \Omega \quad \text{s.t. } \hat{\gamma}^T (k+2) \in \Omega_{0,i} \quad \text{then} \quad \hat{\gamma}^T (k+2) \in \Omega \quad \text{as for time } k+i \quad \text{the following conclusions are obtained}
\]

(11)

\[
\zeta = \{ \hat{\gamma} \hat{\gamma}^T diag(Q_{1,i}, G_{1,i}^{-1}) \hat{\gamma} \} \text{ is invariant ellipsoid for the predicted states of the uncertainty system with a desired control gain } K \text{ satisfying } K = Y_{\text{opt}}.
\]

3.2 Predictive control law design for stochastic networked system

In this subsection, the design of controller will be given, which drives the stochastic system stable and minimizes the value of the objective function. The following theorems shows a procedure which converts the controller design to a solution of an convex optimization problem.

Theorem1: Let \( x(k) = x(k) \) be the state of stochastic uncertainty system measured at time \( k \) and there are not any constraints on the inputs. Supposing the communication link parameter \( \alpha \) and \( \beta = 1 - \alpha \) are given stochastically (satisfy \( 0 < \alpha \leq 1, 0 < \beta \leq 1 \)) and the matrices \( S > 0, R > 0, 0 \leq \gamma \leq 1 \). For the structure uncertainty system, suppose there exists a state feedback control law

such that the worst case MPC objective function $J_{\infty}^p$ is minimized if there exist matrix $Q_0$, $Q_1$, $G_0$, $G_1$, $W_0$, $W_1$, $\bar{T}_0$, $\bar{T}_1$ and $Y$, such that the below convex minimization problem is feasible

$$\min \gamma$$

(16)

Subject to the following inequalities with $i = 1, \ldots, l$

$$\begin{bmatrix}
1 & * & * & * & * \\
T(k) & Q_1 & * & * & * \\
v(k) & 0 & G_1 & * & * \\
S^{1/2}_i x(k) & 0 & 0 & 0 & \gamma I \\
R^{1/2} v(k) & 0 & 0 & 0 & \gamma I
\end{bmatrix} \geq 0$$

(17)

$$\begin{bmatrix}
\bar{Q}_1 & * & * & * & * \\
A_0 Q_1 + B_i Y & 0 & \bar{W}_1 & * & * \\
0 & \bar{T}_1 & * & * & * \\
\bar{Q}_0 T & 0 & 0 & 0 & \gamma S^{-1}_i \\
Y & 0 & 0 & 0 & \gamma R^{-1}
\end{bmatrix} \geq 0$$

(18)

$$\begin{bmatrix}
\bar{Q}_0 & * & * & * & * \\
0 & G_0 & * & * & * \\
0 & \tau G_0 & \bar{T}_0 & * & * \\
0 & \tau G_0 T & 0 & 0 & \gamma S^{-1}_i \\
0 & \tau G_0 T & 0 & 0 & \gamma R^{-1}
\end{bmatrix} \geq 0$$

(19)

$$\begin{bmatrix}
\bar{W}_1 & * & * & * & * \\
0 & \bar{T}_1 & * & * & * \\
0 & \alpha^{1/2} W_1^T & 0 & Q_0 & * & * \\
0 & \alpha^{1/2} W_1^T & 0 & 0 & G_0 & * \\
0 & (1 - \alpha)^{1/2} \bar{T}_1^T & 0 & 0 & G_1 & *
\end{bmatrix} \geq 0$$

(20)

$$\begin{bmatrix}
\bar{W}_0 & * & * & * & * \\
0 & \bar{T}_0 & * & * & * \\
0 & (1 - \beta)^{1/2} W_0^T & 0 & Q_0 & * & * \\
0 & (1 - \beta)^{1/2} W_0^T & 0 & 0 & \bar{Q}_1 & * \\
0 & \beta^{1/2} \bar{T}_0^T & 0 & 0 & \bar{G}_1 & *
\end{bmatrix} \geq 0$$

(21)

Where $T(k) = A_x(k) + B_i v(k)$, if the above minimization problem is feasible, the gain matrices of the predictive controller are given by

$$K = Y \bar{Q}_1^{-1}$$

(22)

Also from the augmented model and the quadratic Lyapunov function, the contractiveness condition can be written as:

$$E_{i(k)} \{ E_{i(k+i)} \tilde{y}(i) + i(k) \bar{Y}^T \Phi \lambda_{i(k+i)} \tilde{y}(i) + i(k) \} - \tilde{y}(i) + i(k)^T \Phi \lambda_{i(k+i)} \tilde{y}(i) + i(k) + E_{i(k)} \{ \tilde{y}(i) + i(k)^T \bar{Y} \} \times \Sigma \bar{y}(i+k) + v(i+k)\bar{Y} \geq 0$$

(23)

Where $\Psi$ taking

$$\begin{bmatrix}
A(k+i) + \lambda(k+i) B_i & \bar{y}(i) + i(k) \bar{K}(1 - \lambda(k+i) \bar{y}(i) + i(k) - \lambda(k+i) \bar{y}(1 - \lambda(k+i) \bar{y})I
\end{bmatrix}$$

(24)

$$\Phi \lambda_{i(k+i)} = \text{diag}\{Q_{\lambda_{i(k+i)}}(k), G_{\lambda_{i(k+i)}}(k)\}$$

$$\Phi \lambda_{i(k+i+k)} = \text{diag}\{Q_{\lambda_{i(k+i+k)}}(k), G_{\lambda_{i(k+i+k)}}(k)\}$$

When $\lambda(k+i) = 1$, inducing the transition matrix $P$ we have $E_{i(k+i+k)-1}(\Phi \lambda_{i(k+i+k)}) = \text{diag}\{Q_0, G_0\} = (1 - \alpha) \text{diag}\{Q_1, G_1\}$, so the (23) is satisfied if the following inequalities hold,

$$\begin{bmatrix}
A(k+i) + B_i & \bar{y}(i) + i(k) \bar{K}
\end{bmatrix}^T \begin{bmatrix}
W_1 & 0 \\
0 & K\bar{T}_0
\end{bmatrix} \begin{bmatrix}
A(k+i) + B_i & \bar{y}(i) + i(k) \bar{K}
\end{bmatrix}$$

(25)

$$\text{diag}\{Q_0, G_0\} + (1 - \alpha) \text{diag}\{Q_1, G_1\} \leq \text{diag}\{W_1, T_1\}$$

(26)

Proof: Based on the compensation strategy, if data dropouts at time $k$, the control law that has been calculated at previous time is used. In fact, the control law at time $\bar{k}$ is assumed to be transmitted successfully, the quadratic function $V$ that we choose is $Q_1$ with $Q_1 = \gamma Q_1^{-1}$, $G_1 = \gamma G_1^{-1}$, using Schur complements, $K$ is equal to $Q_1^{-1}$

$$Q_1^{-1} \text{ diag}\{Q_0, G_0, Q_1, G_1, W_0, \bar{T}_0, W_1, \bar{T}_1, Q_{01}, G_{01}, Q_{02}, G_{02}, Q_{03}, G_{03}\}$$

3.3 Recursive feasibility and stochastic stability of MPC

Theorem 2: The uncertainty model is (1) and (5), for initial time $k = k_0$, it supposes that the control inputs are transmitted from
the controller to the actuator successfully and the optimization problem (10) is feasible. Then the optimization problem is feasible for future time $k \geq k_0$.

Proof: Based on the assumption, the MPC optimization problem is feasible at initial time $k = k_0$ and $\lambda(k_0) = 1$, the only LMI in the problem that influenced explicitly by the measured state $\hat{y}(k|k) = \hat{y}(k)$ of the system is (17). Therefore, to prove the recursive feasibility, it only proves (17) is feasibility for all future states $\hat{y}(k+i|k)$, $(i > 0)$. Assuming that the optimal solution in Theorem2 at time $k_0$ is $\{\gamma^*(k_0)\}V(k_0|k_0) \leq \gamma^*(k_0)$, an optional solution $\{\gamma^*(k_0)\}$ is constructed at time $k = k_0 + 1$. Using lemma1, $V(k_0+1|k_0) \leq \gamma^*(k_0)$, since the optional state measured at time $k_0 + 1$, that is $\hat{y}(k_0 + 1|k_0 + 1) = \hat{y}(k_0 + 1)$, equals $\hat{y}(k_0 + 1|k_0)$, for any $[A(k) B(k)] \in \Theta$, which must satisfy $V(k_0 + 1|k_0 + 1) = V(k_0 + 1|k_0) \leq \gamma^*(k_0)$, thus the feasible solution at time $k_0$ is feasible at time $k_0 + 1$.

At time $k_0 + 2$, two cases will be considered: (i) $\lambda(k) = 1, \lambda(k + 1) = 1$, which means no delays. It assumes that the optional solution at time $k_0 + 1$ is $\{\gamma^*(k_0 + 1)\}V(k_0+1|k_0 + 1) \leq \gamma^*(k_0 + 1)$, using similar analysis at time $k_0 + 1$, $\{\gamma^*(k_0 + 1)\}$ is also feasible at time $k_0 + 2$. (ii) $\lambda(k) = 1, \lambda(k + 1) = 0$, which denotes delays. Since the data delays at time $k_0 + 1$, the control input cannot be transmitted to the actuator accurately, according to the compensation strategy, the control input at time $k_0$ stored in actuator buffer will be applied, so the optional solution $\{\gamma^*(k_0)\}V(k_0|k_0) \leq \gamma^*(k_0)$ is constructed at time $k_0 + 2$ and $V(k_0 + 2|k_0) \leq \gamma^*(k_0)$. Moreover, in such case, the independent state $\hat{y}(k_0 + 2|k_0 + 2) = \hat{y}(k_0 + 2|k_0)$ satisfy the state space equation. Thus it can be derived $V(k_0 + 2|k_0) = V(k_0 + 2|k_0) \leq \gamma^*(k_0)$, that is, $\{\gamma^*(k_0)\}$ is also feasible at time $k_0 + 2$.

As for $k_0 + i \geq 3$, similar conclusions can be derived in the same way.

Theorem3: For the model in (1) and (5), this paper proves the stability of polytopic system and it will refer the previous Lyapunov function $V(k + 1|k) = \hat{y}(k+i|k)^T L_{k+i} \hat{y}(k+i|k)$, where $L_{k+i} = diag\{Q_{\lambda(k+i)} G_{\lambda(k+i)}\}, \lambda(k+i) > 0$ is obtained from optimal problem at time $k_0 + i$. Further, the function $V$ is a strictly decreasing. Considering the real time network with data loss, the optional solution at time $k_0$ is solved in Theorem2 and control sets can be transmitted successfully, due to the recursive feasibility, the optional problem is feasibility for $k > k_0$. Moreover, the convex optimization has a unique minimum and a set of optional solution $\{\gamma^*(k), L_k\}$ at $k > k_0$.

At time $k_0 + 1$, for $\lambda(k_0 + 1) = 0$, which means the optional solution $\{\gamma^*(k_0 + 1)\}$ failure. According to the compensation strategy, the input at time $k_0 + 1$ is dependent on $\{\gamma^*(k_0)\}$, then upper bound of $\gamma(k_0 + 1)$ is $\gamma^*(k_0)$. As for $\lambda(k_0 + 1) = 1$, the optional results from Theorem2 can be transmitted successfully, so

$$\hat{y}(k_0 + 1|k_0 + 1)^T L_{k_0+1} \hat{y}(k_0 + 1|k_0 + 1) \leq \hat{y}(k_0 + 1|k_0 + 1)^T L_{k_0} \hat{y}(k_0 + 1|k_0 + 1)$$

(28)

where $L_{k_0+1}$ is obtained from Theorem2, whereas $L_{k_0}$ is only feasible at time $k_0 + 1$. According to the predictive control law $u(k_0 + s|k_0) = K\hat{y}(k_0 + s|k_0)$ and Lemma1, for $[A(k) B(k)]$ lying in polytope, we have

$$\hat{y}(k_0 + 1|k_0 + 1)^T L_{k_0} \hat{y}(k_0 + 1|k_0 + 1) \leq \hat{y}(k_0|k_0)^T L_{k_0} \hat{y}(k_0|k_0)$$

(29)

Because the independent state $\hat{y}(k_0 + 1|k_0 + 1) = \hat{y}(k_0 + 1)$ equals $(A(k) + B(k)K)\hat{y}(k_0)$, which must satisfy (29). From (28) and (29), we conclude

$$\hat{y}(k_0 + 1|k_0 + 1)^T L_{k_0+1} \hat{y}(k_0 + 1|k_0 + 1) \leq \hat{y}(k_0|k_0)^T L_{k_0} \hat{y}(k_0|k_0)$$

(30)

Therefore, $(\gamma^*(k))^T L_{k_0} \hat{y}(k|k)$ is decreasing function in another words, $\gamma^*(k)$ is decreasing with $k$, that is, $\gamma^*(k_0 + 1) \leq \gamma^*(k_0)$. At time $k_0 + 2$, based on the above similar analysis, the following conclusions can be obtained:

(i) for $\lambda(k_0 + 1) = 0, \lambda(k_0 + 2) = 0$, from Lemma1, the upper bound of $\gamma^*(k_0 + 2)$ is $\gamma^*(k_0)$;

(ii) for $\lambda(k_0 + 1) = 0, \lambda(k_0 + 2) = 1$, based on the optimization principle, we have $\gamma^*(k_0) \leq \gamma^*(k_0 + 2)$;  

(iii) for $\lambda(k_0 + 1) = 1, \lambda(k_0 + 2) = 1$, based on the upper bound of option value $\gamma^*(k_0 + 2)$ is $\gamma^*(k_0 + 1) \leq \gamma^*(k_0)$;  

As for $k_0 + i (i \geq 3)$, similar results can be obtained. Specifically, if there exist $h$ successive data time-delay, the upper bound of $\{\gamma^*(k_0 + h)\}$ is $\{\gamma^*(k_0 + h - h)\}$, if transmitted successfully, $\gamma^*(k_0 + h) = \gamma^*(k_0 + h)$, because the maximum data time-delay is bounded by $h_{max}$, so $\{\gamma^*(k_0)\}$ is decreasing with $k$.

4. ILLUSTRATE EXAMPLE

In this section, a classical angular positioning system (Fig3) is used to prove the effectiveness of proposed design. The system consists of a rotating antenna at the origin of the plane, driven by an electric motor, the aim is to find the input voltage to the motor to rotate the antenna such that it points in the direction of a moving object in the plane. Defining $x(k) = [x^T(k) \ x^T_2(k)]^T = [\theta^T(k) \ \dot{\theta}^T(k)]^T$ and $\theta(k) = \theta_0$. The optimal control problem is to find the control $u(k)$ such that $J(u) = \int_0^\infty \dot{\theta}^2(t) dt$ is minimized.
sampling time $T = 0.1\, \text{s}$, the closed-loop model can be written as follow:

$$x(k + 1) = A(k)x(k) + B(k)v(k)$$

Where

$$A(k) = \begin{bmatrix} 1 & 0.1 \\ 0 & 1 - 0.1\pi(k) \end{bmatrix}$$

And $B = \begin{bmatrix} 0 & 0.1 \end{bmatrix}^T$, where $\pi = 0.787\, \text{rad}^{-1}V^{-1}\, \text{s}^{-2}$.

Fig. 3. data status

the parameter $\pi(k) \in [0.1, 10]$ is proportional to the coefficient of viscous friction and is time varying. So $[A(k) \ B(k)] \in \Theta = Co([A_1 \ B], [A_2 \ B])$, and $A1 = [1, 0.1; 0.99], A2 = [1, 0.1; 0, 0]$, the uncertainty set $\Theta$ is a polytope.

Here, it takes $S_1 = I_2$ and $R = 10^{-6}$, the forgetting factor $\tau = 0.2$ and initial value $x0 = [0.05 \ 0.04]^T, V_{\max} = 2$. Then, consider the upper bound of data loss, it has $\lambda_{\max} = 3$, showing as fig.5.

Fig. 4. system state x1

First, for stochastic network links, it gets the following results by proposed design consider the different missing rate $\{\alpha \ \beta\}$.

Fig. 5. system state x2

Fig. 6. control inputs v

Fig. 7. option value
Specifically, it takes $\alpha$ is 0.06, 0.20, 0.40 and corresponding $\beta$ is 0.94, 0.08, 0.60. Fig.4 and fig.5 are the trajectories of system state $x_1$, $x_2$, respectively. Fig.4 is the system inputs and fig.5 is the control inputs, that is, the Speed of convergence of system is better. Therefore, the following conclusions are obtained: the control law computed by this paper is effectiveness for networked control system with missing data, where missing rate is varying, furthermore, a smaller forgetting factor will improve the performance of controller.

5. CONCLUSION

For the stochastic-networked control system, this paper has presented a robust MPC algorithm for uncertainty models with guaranteed stochastically stable under the bounded data loss. The advantage of this algorithm is providing a state feedback law considering the four aspects as polytoic uncertainty models, stochastic invariant sets, recursive feasibility and stochastic stability. The effectiveness are shown by simulations. Furthermore, the research on robust model predictive control have remained a popular issue for networked control system.
